On Energy Harvesting Gain and Diversity Analysis in Cooperative Communications

Meng-Lin Ku, Wei Li, Yan Chen and K. J. Ray Liu

Abstract—The use of energy harvesting cooperative relays is a promising solution to battery-limited wireless networks. In this paper, we consider a cooperative system in which one source node transmits data to one destination with the assistance of an energy harvesting decode-and-forward relay node. Our objective is to minimize the long-term average symbol error rate (SER) performance through a Markov decision process (MDP) framework. By doing so, we find the optimal stochastic power control at the relay that adapts the transmission power to the changes of energy harvesting, battery, channel and decoding states. We derive a closed-form expression for the exact SER of the cooperative system. Further insights are gained by analyzing the asymptotic SER and its lower and upper bounds at high signal-to-noise ratio (SNR), and the performance is eventually characterized by the occurrence probability of the relay’s actions at the worst channel states in the MDP. We also show that the optimal cooperative policy at asymptotically high SNR follows a threshold-type structure, i.e., the relay spends the harvested energy only when the signal is successfully decoded and the source is faced with the worst channel condition in its direct link. Using these observations to quantify the diversity gain and the energy harvesting gain, we reveal that full diversity is guaranteed if and only if the probability of harvesting zero energy quantum is zero, which can be achieved by reducing the energy quantum size or increasing the energy harvesting capability. Finally, we present several numerical examples to validate the analytical findings.

Index Terms—Energy harvesting, cooperative communication, energy harvesting gain, diversity order.

I. INTRODUCTION

Wireless communications are often vulnerable to small-scale fading caused by multipath channel propagation. In past few years, cooperative communications have gained much interest to mitigate this negative effect through the use of relays to reap the inherent spatial diversity gains [1]. This is particularly attractive when it is unaffordable to install multiple antennas on size-limited communication nodes. Various cooperative techniques have been proposed and analyzed in terms of the outage probability or the symbol error rate (SER), among which decode-and-forward (DF) and amplify-and-forward (AF) are deemed as the most popular ones to provide full diversity gains and to make a more efficient use of transmission power [2], [3]. It has been shown in [1] that the DF protocol, in which the relay first decodes the received signal, re-encodes it and then forwards it to the destination if the decoding is correct, has better performance than the AF protocol, in which the relay simply amplifies the received signal and forwards it.

In many wireless applications, wireless nodes are untethered to an energy infrastructure and can only be powered by batteries with limited capacity. This major limitation requires frequent battery replacement to prolong network lifetime when the battery is exhausted. Such an embarrassment of energy shortage is even challenging for cooperative communications as wireless cooperative nodes are often subject to space limitation to utilize multiple antennas, not to mention the use of a large battery with long lifetime. In addition, the replacement of batteries may be inconvenient, costly or dangerous in some applications, e.g., environmental monitoring in wireless sensor networks. Recently, energy harvesting has become an attractive option to wireless nodes by scavenging ambient energy from environments such as solar, wind, thermoelectric or motion effects, etc [4]. Thus, it is a naturally evolutionary step to consider wireless cooperative nodes powered by energy harvesting devices. In spite of a potentially infinite amount of energy available at nodes, the dynamics of the harvested energy and the limited capacity of rechargeable batteries motivate us to revisit the classical problems of power management and to design more efficient energy usage schemes.

When cooperative communications meet energy harvesting, three interesting questions are raised: (1) Can/How a source that cooperates with an energy harvesting relay node achieve a full diversity gain in reality? (2) What is the optimal relay transmission policy for achieving the full diversity? (3) Except for the diversity gain, what is the impact of energy harvesting on the performance gain in terms of signal-to-noise power ratio (SNR)? In traditional wireless systems, the SNR performance gain is often termed as the coding gain. Here, a new terminology, energy harvesting gain, is introduced instead to emphasize the influence of energy harvesting on the coding gain performance of cooperative communications. While energy harvesting has been extensively investigated in the recent literature, the aforementioned questions have not been fully addressed and remain to be answered, and these questions are important toward understanding the fundamental performance limit of the cooperative networks with energy harvesting capability.

Extensive research efforts have been devoted to energy management problems for various energy harvesting communications [5]–[12]. In [5], the authors investigated a directional water-filling algorithm to maximize the short-term throughput for a wireless link with an energy harvesting transmitter by.
assuming that the harvested energy and channel fading states are known non-causally. By using a deterministic energy harvesting model, packet scheduling problems that aim at maximizing the throughput or minimizing the transmission time were studied in [6] for a point-to-point communication system with an unlimited-capacity battery, while the design was later generalized in [7] with finite energy storage. The work of [8] designed power allocation for throughput maximization over a finite horizon with a preset energy arrival profile. However, all these works require tight prediction on the non-causal side information of energy amount arrivals, and this becomes very challenging when the energy management interval is enlarged. As an alternative, some other works adopted stochastic energy harvesting models under which the energy arrivals are described in a probability sense [8]–[12].

In [8], dynamic programming was employed to find the optimal power allocation scheme that maximizes the throughput according to a Markov random energy harvesting model. When the energy and packet arrivals are formulated as Markov processes, sleep and wake-up strategies were developed for wireless solar-power sensor networks in [10]. The authors in [11] and [12] proposed data-driven stochastic models, and power control and adaptive modulation were jointly designed to maximize the net bit rate through a discounted Markov decision process (MDP).

On the other hand, recent attention has been paid to energy harvesting cooperative communications [13]–[24]. By maximizing the short-term throughput, the authors in [13] investigated directional water-filling power control schemes for an energy harvesting source and a conventional half-duplex relay with constant power in two-hop communication systems. In [14], power allocation problems were addressed for a scenario that both source and half-duplex DF relay nodes are self-sustained with energy harvesting, subject to different data traffic delay constraints. The work in [15] proposed offline and online power allocation algorithms for maximizing throughput in the conventional and buffer-aided single link cooperative systems with energy harvesting source and relay nodes. In [16], the problem of throughput maximization in an energy harvesting two-hop AF relay network was carried out by considering the non-causal or causal knowledge of harvested energy. The optimal energy expenditure schemes were also discussed in [17] and [18] for full-duplex relaying protocols, while two-way relay channels with energy harvesting nodes were considered in [19], [20]. Moreover, when only partial state information about the relay is available at the source node, the transmission scheduling problem was cast as a partially observable Markov decision process (POMDP) in [21]. However, the aforementioned works primarily focused on the data throughput maximization problem and the development of the optimal solution and its property under different network settings. Only few works concentrated on analyzing the outage behavior or the SER performance. In [23], the outage probability for a cooperative network aided by energy harvesting relay nodes was derived based upon a simple on-off stochastic energy harvesting model. In [24], SER performance analysis was performed for relay selection in a cooperative network employing voluntary energy harvesting relays. However, the battery-exhausted probabilities, which depend on transmission actions and stochastic energy arrivals, were assumed to be known in the analysis of these two works, and neither of them discussed the optimal transmission policies for minimizing the outage probability or the SER performance.

Cooperative communications, if successfully implemented, is undoubtedly expected to improve the link quality of wireless networks with energy harvesting. However, a quantitative answer on the impact of energy harvesting on the SER performance as well as the potential diversity gains and energy harvesting gains is still missing. In this paper, we investigate the optimal cooperative transmission policy for an energy harvesting relay node that helps forward the signal from a source node to a destination node via a selective DF protocol. For this purpose, we resort to the MDP as a means to find out the optimal transmission action at the relay with the goal of minimizing the long-term average SER and to analyze the achievable diversity gains and energy harvesting gains of the cooperative networks. Specifically, the novelty and contribution of this paper are summarized as follows:

- A solar-data-driven stochastic energy harvesting model in [12] is utilized in the construction of the MDP design framework, in which the optimal relay transmission policy is designed in order to minimize the long-term average SER performance by adapting the transmission power to the changes of the energy harvesting, battery, channel and decoding states. Unlike the existing works that focus on either finding the optimal solution for the throughput maximization or simply analyzing the outage/SER performance without addressing the optimal transmission policy, the main goal of this paper is to analyze the SER performance of the energy harvesting cooperative communications under a realistic energy harvesting model and to analytically characterize the interplay between the attainable performance and the transmission policy.

- Based on the developed MDP framework, exact and asymptotic SER expressions are derived for the energy harvesting cooperative communications. In particular, we establish the relationship between the asymptotic SER and the occurrence probability for the adopted relay action in the MDP. Furthermore, we analyze upper and lower bounds for the asymptotic SER to quantify the diversity gains as well as the energy harvesting gains of the considered cooperative transmission policy. By theoretical analysis, a theorem regarding the accessibility of a diversity order of two is provided, and it reveals that the full diversity is achievable only if the stationary probability of the relay’s actions at the worst channel states for which the decoding is successful but the relay keeps silent goes to zero. To the best of our knowledge, this is the first attempt to comprehensively study the diversity gains and energy harvesting gains of the optimal stochastic transmission policies by means of the MDP.

- We then uncover that the optimal cooperative transmission policy at asymptotically high SNR is degenerated into a threshold-type policy. That is, the relay with non-empty battery spends the harvested energy only when the source node stays at the worst channel condition in its direct link and the relay node can successfully decode the signals.

With this elegant characteristic, we further explore an energy
quantum supporting way, along with the promising structures of policies, for achieving the full diversity order. Our analysis shows that the fully diversity can be reached if and only if the energy quantum outage probability, i.e., the probability of obtaining zero energy quantum, is equal to zero. By linking this result to the solar-data-driven energy harvesting model in [12], we prove that a zero energy quantum outage probability is attainable if a ratio between the energy quantum size and the energy harvesting capability is considerably small. Finally, some numerical examples are offered to justify the analytical derivations and the proposed theorems in this paper.

The rest of this paper is organized as follows. In Section II, we introduce the selective DF cooperative networks with energy harvesting. In Section III, an MDP design framework for finding the optimal cooperative transmission policy is presented, and the main structure results of the policy are also discussed. Section IV is devoted to derive the exact SER and the asymptotic SER, followed by the analysis of the diversity gains and the energy harvesting gains. Furthermore, we address the optimal policy at asymptotically high SNRs and the energy supporting condition for achieving the full diversity. Numerical results are presented in Section V, and conclusions are drawn in Section VI.

II. ENERGY HARVESTING COOPERATIVE COMMUNICATIONS

We consider a cooperative relay network in Fig. 1, where a source (S) and a destination node (D) communicate over a wireless fading channel with the assistance of an energy harvesting relay node (R). The relaying protocol involves two signal transmission phases, and the time duration of each phase is $T_P$. Define $h_{sr}$ and $h_{sd}$ as the channel coefficients from the source to the relay and the destination, respectively, and $h_{rd}$ as the channel from the relay to the destination. Further, the channels $h_{sr}$, $h_{sd}$, and $h_{rd}$ are complex white Gaussian random variables with zero mean and variance $\eta_{sr}$, $\eta_{sd}$ and $\eta_{rd}$. Let $x$ be the $M$-ary phase-shift-keying (M-PSK) data modulated symbol of the source node, where $\mathbb{E} \left[ |x|^2 \right] = 1$ and the operator $\mathbb{E} \left[ \cdot \right]$ takes the expectation. In the first phase, the source sends the information to the destination, and meanwhile, the information is received by the relay node. The received signals can be expressed as

$$y_{sd} = \sqrt{P_s} h_{sd} x + z_d;$$

$$y_{sr} = \sqrt{P_s} h_{sr} x + z_r,$$

where $z_d$ and $z_r$ are additive complex white Gaussian noise with zero mean and variance $N_0$, and $P_s$ is the transmission power of the source node. From (1) and (2), the instantaneous SNRs at the relay and the destination can be calculated as

$$\Upsilon_{sd} = \frac{P_s |h_{sd}|^2}{N_0};$$

$$\Upsilon_{sr} = \frac{P_s |h_{sr}|^2}{N_0},$$

where we define $\zeta_{sd} = |h_{sd}|^2$ and $\zeta_{sr} = |h_{sr}|^2$ as the instantaneous channel power. In the second phase, the relay can decide whether to forward the decoded data symbol $\hat{x}$ with transmission power $P_r$ or to keep silent with zero power consumption. In this paper, a selective DF strategy in [3] is adopted, and the relay can help forward the re-encoded data symbols, only if it can decode the received data symbols correctly. In practice, this can be implemented by considering an SNR threshold at the relay, and it is reasonable to assume that the relay can successfully decode the data symbols with a negligible error probability if the instantaneous SNR of its received signal is larger than a preset threshold. Hence, the received signal at the destination is written as

$$y_{rd} = \sqrt{P_r} h_{rd} x + \tilde{z}_d,$$

where $\tilde{z}_d$ stands for the noise in the second phase with the same statistic as $z_d$, $P_r$ is the relay transmission power, and $P_r \neq 0$ if the data symbol is correctly decoded and forwarded to the destination by the relay; otherwise, $P_r = 0$.

We assume that the channel state information (CSI) of the wireless links $h_{sd}$ and $h_{rd}$ can be perfectly estimated by the destination node. With the CSI knowledge, a maximum ratio combining (MRC) scheme is utilized for combining the received signals (1) and (5) of the two phases at the destination:

$$y_c = c_1 y_{sd} + c_2 y_{rd}.$$

By applying the combining weights $c_1 = \sqrt{P_r h_{sd}^* / N_0}$ and $c_2 = \sqrt{P_r h_{rd}^* / N_0}$ into (6), the SNR of the output of the combiner $y_c$ can be further calculated as

$$\Upsilon_c = \frac{P_s \zeta_{sd} + P_r \zeta_{rd}}{N_0}.$$

III. STOCHASTIC RELAY TRANSMISSION POLICY USING MARKOV DECISION PROCESS

The design of the relay transmission policy depends on a couple of factors, like channel conditions $H_{rd}$ and $H_{sd}$ of the wireless links among nodes, battery condition $Q_b$, energy harvesting condition $Q_e$, and decodability of the relay node $Q_c$. Our goal is to find the optimal transmission policy by formulating the problem as an average SER minimization.
problem through the MDP, while concerning a limited battery recharging rate. Moreover, we intend to study the diversity and energy harvesting gains of the policy which can be formally defined as follows:

Definition 1: Let \( \gamma \) and \( P_{SER}(\gamma) \) be the SNR and the SER, respectively. At asymptotically high SNR, if the SER is expressed as \( P_{SER} \sim (g_E \cdot \gamma)^{-d} \), the constants \( g_E \) and \( d \) are the energy harvesting gain and the diversity order of the cooperative communications.

Consider a five-tuple state space \( s = (H_{rd}, H_{sd}, Q_b, Q_c, Q_e) \in S_{rd} \times S_{sd} \times Q_b \times Q_c \times Q_e \triangleq S \), where \( S_{rd} = \{0, \ldots, N_{rd} - 1\} \), \( S_{sd} = \{0, \ldots, N_{sd} - 1\} \), \( Q_b = \{0, \ldots, N_b - 1\} \), \( Q_c = \{0, \ldots, N_c - 1\} \), and \( Q_e = \{0, 1\} \). The policy is managed on the time scale of \( T_M \) which covers a number of two-phase transmissions. For each state, the relay can select to forward the information from the source to the destination by adjusting its transmission power level or just to keep silent. Detailed descriptions of these sates and actions are provided in the following.

A. Channel States

The instantaneous channel power of \( \zeta_{rd} \) and \( \zeta_{sd} \), which correspond to the relay-to-destination (RD) and source-to-destination (SD) links, can be quantized into several levels, given by \( \Gamma_{rd} = \{0 = \Gamma_{rd}^{(0)}, \Gamma_{rd}^{(1)}, \ldots, \Gamma_{rd}^{(N_{rd})} = \infty\} \) and \( \Gamma_{sd} = \{0 = \Gamma_{sd}^{(0)}, \Gamma_{sd}^{(1)}, \ldots, \Gamma_{sd}^{(N_{sd})} = \infty\} \), respectively. By ignoring the subscript of the notations “rd” and “sd”, we say a channel \( \zeta \) is in the \( j \)th state, if \( \Gamma(j) \leq \zeta < \Gamma(j+1) \), for \( j = 0, \ldots, N-1 \). Furthermore, we assume that the channel gain is quasi-static during the policy management period \( T_M \), and the channel can only transit from the current state to its neighboring states. The stationary probability of the \( j \)th channel state can be computed as

\[
P(H = j) = \frac{1}{\eta} \exp\left(-\frac{\zeta}{\eta}\right) d\zeta \quad (8)
\]

where \( \eta = \mathbb{E}[\zeta] \) is the average channel power. Define a function \( h(\zeta) = f_D \sqrt{2\pi \zeta / \eta} \exp(-\zeta / \eta) \), where \( f_D \) is the maximum Doppler frequency, normalized by the policy management period \( T_M \). The state transition probabilities are then determined by [25]

\[
P(H = j'|H = j) = \begin{cases} \frac{h(\Gamma(j+1))}{P(H=j')}, & j' = j + 1, \ j = 0, \ldots, N - 2; \\ \frac{h(\Gamma(j))}{P(H=j')}, & j' = j - 1, \ j = 1, \ldots, N - 1; \\ 1 - \frac{h(\Gamma(j))}{P(H=j')}, & j' = j, \ j = 1, \ldots, N - 2, \end{cases}
\]

and the transition probabilities of \( P(H = j|H = j) \) at the boundary states are given by

\[
P(H = 0|H = 0) = 1 - P(H = 1|H = 0); \\ P(H = N - 1|H = N - 1) = 1 - P(H = N - 2|H = N - 1). \quad (10)
\]

B. Decoding States

Two decoding states are taken into consideration in the MDP: “Success” and “Fail”. If \( Q_c = 1 \), it means that data symbols are correctly decoded by the relay during the first phase. On the contrary, the state \( Q_c = 0 \) indicates that the relay fails to decode the message from the source. In general, the decoding probability can be characterized by the instantaneous SNR of the source-to-relay (SR) link \( P_{SR} \), and the decoding capability of the relay node which is specified by a threshold \( \gamma \). We say that data symbols can be decoded if \( P_{SR} \geq \gamma \), and it is noted that the relay with a smaller threshold has relatively better decoding capability. For simplicity, the channel variations of the SR link are assumed to be independent across the management periods but quasi-static within the period. Thus, the transition probability of the decoding states is irrelevant to the previous state, and it can be expressed as

\[
P(Q_c = m'|Q_c = m) = \begin{cases} P\left(\zeta_{sr} \geq \frac{\gamma N_{c}}{P_{SR}}\right) = \exp\left(-\frac{\gamma N_{c}}{P_{SR}}\right), & m' = 1; \\ 1 - \exp\left(-\frac{\gamma N_{c}}{P_{SR}}\right), & m' = 0. \end{cases}
\]

C. Relay Actions

Let \( P_r = a G \), where \( G \) is a constant transmission power level. We consider \( N_a \) possible actions for the relay node in the second phase, i.e., \( a \in A = \{0, \ldots, N_a - 1\} \), and the relay complies with the selective DF strategy while playing these actions. When \( a \neq 0 \), it means that the relay selects to help forward the information by consuming a total amount of \( \frac{a}{2} GT_M \) energy in the battery; otherwise, the relay takes no action.

D. Energy Harvesting States

A solar-data-driven energy harvesting model in [12] is adopted here. We assume that there are \( N_e \) underlying energy harvesting states, each of which stands for a meaningful energy harvesting condition like "Excellent", "Good", "Bad", etc. Each state is governed by a state transition probability \( P(Q_e = l'|Q_e = l) \), for \( l, l' = 0, \ldots, N_e - 1 \), and it is associated with an energy harvesting probability in terms of the number of energy quanta that can be obtained from the solar power during the management period \( T_M \). Here, one energy quantum, \( E_U \), is defined as the total amount of energy with respect to the transmission power \( G \) during half the management period \( \frac{1}{2} T_M \), i.e., \( E_U = \frac{1}{2} GT_M \). In other words, the relay action is also operated in units of energy quanta. At the \( l \)th state, the probability of harvesting \( w \) energy quanta is given by \( P(E = w|Q_e = l) \), for \( l = 0, \ldots, N_e - 1 \) and \( w = 0, \ldots, \infty \).

E. Battery States

The battery state transition is determined by both the transmission action and the number of harvested energy quanta at the relay. While \( Q_e = 1 \), the feasible action set at the \( b^{th} \) battery state is given as \( A_{1,b} = \{0, \ldots, \min\{b, N_a - 1\}\} \), since the maximum number of affordable energy quanta is
subject to $b$. Otherwise, $A_{0,b} = \{0\}$ for $Q_e = 0$. When the action $a$ is taken and the number of harvested energy quanta is $w$, the battery state will transit from the state $b$ to the state $b' = \max(b-a+w,N_b-1)$ due to the finite battery storage capacity. Hence, the battery state transition probability at the $t^{th}$ energy harvesting state is given by

$$P_a (Q_b = b' | Q_b = b, Q_e = l) = \begin{cases} P(E = b' - b + a | Q_e = l), & b' < N_b - 1; \\ P(E \geq N_b - 1 - b + a | Q_e = l), & b' = N_b - 1, \end{cases}$$  

which can be implemented by a value iteration algorithm as follows:

$$V_{n+1} (s) = R^n (s) + \lambda \max_{s' \in S} \{ V_n (s') \},$$  

and

$$V_{n+1} (s) = \max_{a \in A_{m,b}} \{ V_n (a) \},$$

where the state transition probability, $P_a (s' | s)$, is given by

$$P_a (s' = (j', k', b', l', m')) = \begin{cases} P (H_{rd} = j' | H_{rd} = j) P (H_{sd} = k' | H_{sd} = k) \\ \cdot P(Q_e = l' | Q_e = l) P (Q_e = m' | Q_e = m) \\ \cdot P_a (Q_b = b' | Q_b = b, Q_e = l). \end{cases}$$

Without loss of generality, the value of $V_0 (s)$ in (18) can be initialized as zero. For the purpose of simple notations, an expectation form for the summation term in (18) will be used in the subsequent sections by applying (12) and (20) and making changes of variables:

$$\sum_{s' \in S} P_a (s' | s) V_n (s') = \sum_{j', k', l', m'} P (H_{rd} = j' | H_{rd} = j) P (H_{sd} = k' | H_{sd} = k) \cdot P(Q_e = l' | Q_e = l) P (Q_e = m' | Q_e = m) \cdot \sum_{w=0}^{\infty} P (E = w | Q_e = l) \cdot V_n (s = (j', k', \min(b-a+w,N_b-1), l', m')) \triangleq \mathbb{E}_{j',k',l,m} [V_n (s = (j', k', \min(b-a+w,N_b-1), l', m'))].$$

H. Main Structure Results of Optimal Relay Transmission Policy

Some important properties of the optimal relay transmission policy are discussed in this subsection. These fundamental results are helpful when we analyze the SER performance in the next section, even though some of these have been explored in various MDP problems. First, we point out that when the battery of the relay contains more residual energy, the cooperative transmission has a larger value of $V_n (s)$, making less contribution to the overall SER performance degradation.

**Theorem 1:** For a fixed channel, energy harvesting and decoding state $(H_{rd}, H_{sd}, Q_e, Q_c) = (j, k, l, m)$, at the $n^{th}$ iteration, we have $V_n (s = (j, k, b, l, m)) \geq V_n (s = (j, k, b', l, m))$, for $b \geq b'$.

**Proof:** To prove this theorem, we need to first show that

$$V_n (a) (s = (j, k, b, l, m)) \geq V_n (a) (s = (j, k, b - 1, l, m)),$$

for any $a \in A_{m,b-1}$ and $b \geq 1$. This result can be proved by induction. When $n = 1$, we get $V_1 (a) (s = (j, k, b, l, m)) = V_1 (a) (s = (j, k, b - 1, l, m)) = R^n (s = (j, k, b, l, m))$, because $V_0 (s = (j, k, b, l, m)) = 0$ and the reward function only depends on the channel state and the relay action. Assuming that $n = i$ holds for any $j \in S_{rd}$, $k \in S_{sd}$,
\[ P^{(a)}( \bar{x} \neq x | H_{rd}, H_{sd}, Q_b, Q_c) = (j, k, b, l), \bar{x} = x) \triangleq \frac{P^{(a)}((H_{rd}, H_{sd}) = (j, k), \bar{x} \neq x | \bar{x} = x)}{P(H_{rd} = j) P(H_{sd} = k)} \]

\[ = \frac{1}{P(H_{rd} = j) P(H_{sd} = k)} \cdot \frac{1}{\pi} \int_{0}^{(M-1)\pi} \int_{0}^{r_{rd}^{(j+1)}} \int_{0}^{r_{sd}^{(k+1)}} \exp\left(-\frac{c_M (P_s \cdot \psi + \alpha G_{\psi})}{N_0 \sin^2 \theta}\right) \cdot p(\psi) \cdot d\psi \cdot d\omega \cdot d\theta. \]

\[ P(\bar{x} \neq x | H_{sd} = k) = \frac{1}{P(H_{sd} = k)} \cdot \frac{1}{\pi} \int_{0}^{(M-1)\pi} \int_{0}^{r_{sd}^{(k+1)}} \exp\left(-\frac{c_M P_s \cdot \psi}{N_0 \sin^2 \theta}\right) \cdot p(\psi) \cdot d\psi \cdot d\omega \cdot d\theta. \]

\( l \in Q_c \) and \( m \in Q_c \), we have \( V^{(a)}_i(s) = (j, k, b-1, l, m)) \leq \]

\( V^{(a)}_i(s) = (j, k, b, l, m), \) for all \( b \in Q_b \setminus \{0\} \). It implies that

\[ V_i(s) = (j, k, b, l, m) = \max_{a \in A_{m,b}} \left\{ V^{(a)}_i(s) = (j, k, b, l, m) \right\} \]

\[ \geq \max_{a \in A_{m,b-1}} \left\{ V^{(a)}_i(s) = (j, k, b-1, l, m) \right\} = V_i(s) = (j, k, b-1, l, m). \] (23)

Using (18) and (21), we then prove that for \( n = i + 1 \):

\[ V^{(a)}_{i+1}(s) = (j, k, b, l, m)) \]

\[ = \lambda \cdot E_{j,k,l,m} \left[ V_i(s) = (j', k', \min(b - a + w, N_b -1), l', m') \right] \]

\[ - V_i(s) = (j, k', \min(b - a + w, N_b -1), l', m') \]

\[ \geq 0. \] (24)

Similar to (23), it follows that \( V^{(a)}_{i+1}(s) = (j, k, b, l, m)) \geq \]

\( V^{(a)}_{i+1}(s) = (j, k, b-1, l, m)), \) for \( b \geq 1. \]

The simplicity of a structural policy makes it attractive for hardware implementation in power-hungry energy harvesting relay nodes. Typically, two types of structures are discussed for the optimal policy in the literature, and they are defined in the following [12, 27].

**Definition 2:** A policy is called a threshold-type policy in the battery states with the threshold \( \epsilon(j, k, l, m), \) if

\[ \pi(s) = (j, k, b, l, m)) = \begin{cases} 0, & b \leq \epsilon(j, k, l, m) ; \\ 1, & \not\in 0, \text{ otherwise}, \end{cases} \] (25)

for any fixed \( j \in S_{rd}, k \in S_{rd}, l \in Q_c, \) and \( m \in Q_c. \)

**Definition 3:** A policy is called a monotonic-type policy in the battery states, if

\[ \pi(s) = (j, k, b-1, l, m)) \leq \pi(s) = (j, k, b, l, m)) \], (26)

for any fixed \( j \in S_{rd}, k \in S_{rd}, l \in Q_c, \) and \( m \in Q_c. \)

When the allowable relay action is binary, i.e., \( N_a = 2, \) one can easily prove that the optimal relay transmission policy follows an elegant threshold structure along with the direction of the battery states, where the relay node helps forward the signals only when its instantaneous battery state is above a threshold under given channel, energy harvesting and decoding states, and the following theorem is given.

**Theorem 2:** For \( N_a = 2, \) the optimal relay transmission policy is a threshold-type policy (or equivalently, a monotonic-type policy in this special case).

**Proof:** This can be proved by showing that \( V^{(1)}_n(s) = (j, k, b, l, m)) \) is a non-decreasing function in \( b \in Q_b \) via the induction method, and the details can be referred to a similar proof for Theorem 2 in [12].

While the relay action is not limited to a binary case, the optimal policy could exhibit a monotonic structure in the battery states. A common method to assess the existence of such a monotonic-type structure is to check whether the function \( V^{(a)}_n(s) = (j, k, b, l, m)) \) is supermodular in \( a \) and \( b \) or not, i.e., \( V^{(a)}_n(s) = (j, k, b, l, m)) \) is a non-decreasing function in \( b \in Q_b \) via the induction method, and the details can be referred to a similar proof for Theorem 2 in [12].
IV. PERFORMANCE ANALYSIS

A. Exact SER Expressions

To evaluate the performance of the optimal relay transmission policy, the exact SER of the energy harvesting cooperative communications is analyzed by calculating the stationary state probabilities of the MDP. Consider an optimal policy \( \pi^* (s) \), and denote \( p \) as the corresponding stationary state probability vector of the MDP whose \( (m (N_b N_d N_d N_c) + l (N_b N_d N_d) + k (N_b N_c) + j N_b + b) \) th entry, \( p_{j,k,b,l,m} \), stands for the stationary probability of the state \((H_{rd}, H_{sd}, Q_b, Q_c) = (j, k, b, l, m)\). In addition, let \( M_{j,k,b,l,m} \) be an \( N_b \times N_b \) battery state transition probability matrix at the state \((H_{rd}, H_{sd}, Q_b, Q_c) = (j, k, l, m)\) with respect to the policy \( \pi^* (s) \), and the matrix is specified as

\[
\begin{bmatrix}
M_{j,k,b,l,m}\end{bmatrix}_{b',b} = \begin{cases}
P (E = b' - b + \pi^* (s) | Q_c = l), & b' \leq N_b - 2; \\
0, & b' = N_b - 1,
\end{cases}
\]

where \([M_{j,k,b,l,m}]_{b',b}\) is the transition probability from the battery state \(b\) to \(b'\), corresponding to the optimal policy. Thus, the stationary probabilities are computed by solving the balance equation as follows:

\[
\begin{bmatrix}
1 \\
M^T \\
1
\end{bmatrix}
\begin{bmatrix}
p \end{bmatrix} =
\begin{bmatrix}
p \end{bmatrix},
\]

where 1 is an all-one column vector, and \( M \) is an entire MDP state transition probability matrix, the \((m' (N_r N_d N_d N_c) + l' (N_r N_d N_d) + k' (N_r N_d N_c) + l (N_r N_d N_d) + k (N_r) + j')\) th sub-matrix of which is given as

\[
P (H_{rd} = j' | H_{rd} = j) \cdot P (H_{sd} = k') \cdot P (Q_c = l') \cdot P (Q_c = m) = \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{m=0}^{N_b-1} p_{j,k,b,l,m} \cdot \pi^* (s) (\tilde{x} = x | s = (j, k, b, l, m)).
\]

From (13) and (28), the exact SER is expressed as

\[
P_{M,exact} = \sum_{j=0}^{N_r-1} \sum_{k=0}^{N_d-1} \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{m=0}^{N_b-1} p_{j,k,b,l,m} \cdot \pi^* (s) (\tilde{x} = x | s = (j, k, b, l, m)).
\]

B. Asymptotic Approximations and Bounds for SER Expressions

Here we first analyze the SER expression at asymptotically high SNR. For simplicity of notation, we denote the stationary state probability of the zeroth channel state for the channel link \(x\) in (8) as \(\mu_x\), where \(x\) could be “rd” or “sd”. Let \(\gamma_x\) be the occurrence probability for the action \(a\) at the zeroth states of the SD and RD channels, and it is defined as \(\gamma_x = \sum_{m=0}^{1} \sum_{s \in \Omega_{m,a}} \rho_s\), where \(\Omega_{m,a} = \{ s = (0,0,b,l) \} \). The following theorem is given.

Theorem 3: The asymptotic SER is expressed as

\[
P_{M,asym.} = \sum_{s=0}^{N} K_0 (0) \sum_{N_0} \frac{P_{s}}{N_0} - 1\]

where \(K_0 (0) = \frac{M-1}{\pi} \sum_{N_0} \frac{\sin(2\pi/N_0)}{\sin(4\pi/M)} = \frac{a}{\pi} \sum_{N_0} \frac{\sin(2\pi/N_0)}{\sin(4\pi/M)}
\]

The proof of the above theorem follows from the asymptotic behavior of the stationary probability of the state \((H_{rd}, H_{sd}, Q_b, Q_c) = (j, k, b, l, m)\) as the SNR becomes large. Thus, the SER is approximated as

\[
P_{M,exact} \approx \sum_{s=0}^{N} K_0 (0) \sum_{N_0} \frac{P_{s}}{N_0} - 1\]

where \(K_0 (0) = \frac{M-1}{\pi} \sum_{N_0} \frac{\sin(2\pi/N_0)}{\sin(4\pi/M)} = \frac{a}{\pi} \sum_{N_0} \frac{\sin(2\pi/N_0)}{\sin(4\pi/M)}
\]

Thus, the stationary probabilities are computed by solving the balance equation as follows:

\[
\begin{bmatrix}
1 \\
M^T \\
1
\end{bmatrix}
\begin{bmatrix}
p \end{bmatrix} =
\begin{bmatrix}
p \end{bmatrix},
\]

where 1 is an all-one column vector, and \( M \) is an entire MDP state transition probability matrix, the \((m' (N_r N_d N_d N_c) + l' (N_r N_d N_d) + k' (N_r N_d N_c) + l (N_r N_d N_d) + k (N_r) + j')\) th sub-matrix of which is given as

\[
P (H_{rd} = j' | H_{rd} = j) \cdot P (H_{sd} = k') \cdot P (Q_c = l') \cdot P (Q_c = m) = \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{m=0}^{N_b-1} p_{j,k,b,l,m} \cdot \pi^* (s) (\tilde{x} = x | s = (j, k, b, l, m)).
\]

From (13) and (28), the exact SER is expressed as

\[
P_{M,exact} = \sum_{j=0}^{N_r-1} \sum_{k=0}^{N_d-1} \sum_{b=0}^{N_b-1} \sum_{l=0}^{1} \sum_{m=0}^{N_b-1} p_{j,k,b,l,m} \cdot \pi^* (s) (\tilde{x} = x | s = (j, k, b, l, m))
\]

We can further simplify the factor \(K_0 (0)\) as follows:

\[
K_0 (0) = \frac{1}{\pi} \sum_{j=0}^{(M-1)/2} \sin^2 \theta \exp \left( -c_M P_t \Gamma_{rd} \right) - \exp \left( -\frac{c_M P_t \Gamma_{rd}}{N_0 \sin^2 \theta} \right) d\theta.
\]
where the first and second approximations work well, if \( P_{r} / N_{0} \gg 1 \) and the channel is quantized rationally, i.e., \( \Gamma_{sd}^{(k+1)} - \Gamma_{sd}^{(k)} \geq \varepsilon \) for a sufficiently large \( \varepsilon \). Furthermore, by assuming that \( G / N_{0} \gg 1 \), the factor \( K_{1}^{(k,j)} \) can be approximated in a similar way:

\[
K_{1}^{(k,j)} \approx \left\{ \begin{array}{ll}
\frac{1}{\pi} \int_{0}^{(M-1)\pi} \sin^{2} \theta d\theta - \frac{\sin(2\pi/M)}{4\pi} & \text{if } k = 0, j = 0; \\
0, & \text{otherwise}.
\end{array} \right.
\]

Theorem 4: The sum of the occurrence probabilities \( \varsigma_{a} \) is equal to \( \sum_{a=0}^{N_{a}-1} \varsigma_{a} = \mu_{sd} + \mu_{rd} \). Furthermore, the inactive probability \( \varsigma_{0} = \mu_{rd} P_{c}(Q_{c} = 0) \) and the active probability \( \varsigma_{a} = \mu_{sd} + \mu_{rd} P_{c}(Q_{c} = 1) \), where \( a = \sum_{x \in Q_{a}, p_{x} > 0} \) is the stationary state probability at the zeroth channel states for which the decoding is successful but the relay keeps silent.

Proof: From the balance equation in (28), the stationary state probability satisfies

\[
P_{\pi}^{*}(s) = (j,k,b,l,m) \mid (j,k,b,l,m) \cdot p_{j,k,b,l,m}.
\]

Define \( \tilde{P}_{j,k,m} = \sum_{b=0}^{N_{b}-1} \sum_{l=0}^{N_{l}-1} p_{j,k,b,l,m} \). Using (20) and taking summation over the indices \( b' \) and \( l' \) on the both sides of the equality in (40), we can get

\[
\tilde{P}_{j',k',m} = \sum_{j=0}^{N_{rd}-1} \sum_{k=0}^{N_{sd}-1} \sum_{m=0}^{1} P(H_{rd} = j' | H_{rd} = j) \cdot P(H_{sd} = k' | H_{sd} = k) P(Q_{c} = m' | Q_{c} = m) \cdot \tilde{P}_{j,k,m}.
\]

because \( \sum_{b'=0}^{N_{b'}-1} \sum_{l'=0}^{N_{l'}-1} \sum_{m=0}^{1} P_{\pi}^{*}(s) \cdot (Q_{b'} = b' | \tilde{P}_{b'} = b, Q_{l'} = l) = 1 \). Then, it is concluded from (41) that \( \tilde{P}_{j,k,m} \) is the stationary state probability for the state \( (H_{rd}, H_{sd}, Q_{c}) = (j, k, m) \), and it implies that \( \tilde{P}_{0,0,m} = \mu_{sd} P_{c}(Q_{c} = m) \) because the transitions of the channel and decoding states are independent of each other. We can therefore obtain \( \sum_{a=1}^{N_{a}-1} \varsigma_{a} = \tilde{P}_{0,0,0} + \tilde{P}_{0,0,1} = \mu_{sd} P_{c}(Q_{c} = m) \). Hence, the action \( a = 0 \) is the only action for the relay when the decoding fails, it can be further shown that \( \varsigma_{0} = \tilde{P}_{0,0,0} + \rho \leq \tilde{P}_{0,0,1} \).

In fact, the stationary state probability \( \rho \) plays an important role in the achievable performance, and for a given policy, the probability mainly depends on the energy harvesting capability of the relay node. To get more insight into the performance behavior, an upper bound and a lower bound for the asymptotic SER are provided in the following theorem.

Theorem 5: Assume \( G = c_{r} P_{s} \). For sufficiently high SNR, the asymptotic SER is upper and lower bounded by

\[
\Phi(N_{a} - 1) \leq P_{M,\text{asymp}} \leq \Phi(1),
\]

where the function \( \Phi(z) \) is defined as

\[
\Phi(z) = \frac{\rho K_{0}^{(0)}}{c_{r} \mu_{sd} \mu_{rd} \eta_{rd}} \left( \frac{P_{c}}{N_{0}} \right)^{-1} + \frac{\mu_{rd} \gamma K_{0}^{(0)}}{c_{r} \mu_{sd} \mu_{rd} \eta_{rd}} \left( \frac{P_{c}}{N_{0}} \right)^{-2} - \frac{\gamma K_{0}^{(0)}}{c_{r} \mu_{sd} \mu_{rd} \eta_{rd}} \left( \frac{P_{c}}{N_{0}} \right)^{-3}.
\]

Proof: First, the weighted sum of the active probability \( \sum_{a \neq \frac{N_{a}}{2}} \varsigma_{a} \) is bounded by \( \frac{1}{N_{a} - 1} \sum_{a \neq \frac{N_{a}}{2}} \varsigma_{a} \leq \frac{1}{N_{a} - 1} \sum_{a \neq \frac{N_{a}}{2}} \varsigma_{a} \leq 1 \). Moreover, by using \( e^{x} \approx 1 + x \) for \( x \ll 1 \), when \( P_{c} / N_{0} \gg \gamma \), the successful decoding probability in (11) can be approximated as \( P(Q_{c} = 1) = 1 - \gamma P_{c} / N_{0} \). Let \( G = c_{r} P_{s} \). By applying the above results and Theorem 4 into (31), we can obtain the upper bound and the lower bound for the asymptotic SER as shown in (42).

It is noted from Theorem 5 that the equality in (42) holds only when two kinds of actions, either keeping silent or transmitting with a constant power level \( G \), are accessible to the relay node. In this case, the bounds are tight and \( P_{M,\text{asymp}} = \Phi(1) \). Another condition for which the lower and upper bounds get closer at extremely high SNR values of \( P_{c} / N_{0} \) is when the stationary state probability \( \rho \) is not equal to zero. In this case, the function \( \Phi(z) \) is dominated by the first term in (43).

C. Diversity Order and Energy Harvesting Gain

The main idea behind cooperative communications is to form a virtual multiple-input multiple-output (MIMO) system
via separated single-antenna nodes, and it is interesting to investigate the diversity order in such an energy-limited relay network when the SNRs of the three channel links go to infinity. In addition to the diversity order, the energy harvesting gain is another important metric to characterize the performance of energy harvesting cooperative networks.

**Theorem 6**: If \( \rho > 0 \), the diversity order and the energy harvesting gain of the cooperative communications are respectively given as \( d = 1 \) and \( g_E = \frac{CM\rho^K_0 \rho_{sd}N_0^d}{P_D} \). When \( \rho = 0 \), a full diversity \( d = 2 \) is achieved and the energy harvesting gain is bounded by

\[
\left( \frac{N_0-1}{N_0} \right)^{\frac{1}{c_3^E \rho_{sd} N_0^d d}} \leq g_E \leq \left( \frac{N_0-1}{N_0} \right)^{\frac{1}{c_3^E \rho_{sd} N_0^d d} + \frac{1}{\mu_{sd} CM P_{sd} \rho_{sd}}}.
\]

**Proof**: From Theorem 5, if \( \rho > 0 \), the SER for sufficiently high SNR is dominated by the first term in (43), and it can be approximated as

\[
P_{M,asym} \approx \frac{K_0^{(0)}}{c_3^E \rho_{sd} N_0^d} \left( \frac{\rho_{th}}{N_0} \right)^{-1}.
\]

Therefore, the diversity order is one and the energy harvesting gain is \( g_E = \frac{CM\rho^K_0 \rho_{sd} N_0^d}{P_D} \). As \( \rho = 0 \), the SER is dominated by the second term in (43) when \( \frac{\rho_{th}}{N_0} \to \infty \), resulting in a diversity order of two, and the energy harvesting gain is lower and upper bounded by

\[
\left( \frac{N_0-1}{N_0} \right)^{\frac{1}{c_3^E \rho_{sd} N_0^d d}} \leq g_E \leq \left( \frac{N_0-1}{N_0} \right)^{\frac{1}{c_3^E \rho_{sd} N_0^d d} + \frac{1}{\mu_{sd} CM P_{sd} \rho_{sd}}}.
\]

The aforementioned discussions raise an interesting question on the prospects for achieving the full diversity order of two. In fact, whether the full diversity order is achievable directly depends on the energy quantum harvesting probability \( P(E = w | Q_e = l) \) and the optimal policy at asymptotically high SNR. Before introducing the condition of the energy quantum supporting way for achieving \( d = 2 \), we specify the optimal cooperative transmission policy at asymptotically high SNR with the following theorem.

**Theorem 7**: When \( \frac{N_0}{\rho_{th}} \to \infty \), the optimal cooperative transmission policy \( \pi^*(s) \) at asymptotically high SNR is a threshold-type policy, which is given by

\[
\varepsilon(j,k,l,m) = \begin{cases} 
0, & k = 0, m = 1; \\
N_0 - 1, & \text{otherwise}.
\end{cases}
\]

**Proof**: From (34) and (37)-(39), when \( \frac{N_0}{\rho_{th}} \to \infty \), the reward function (13) at asymptotically high SNR becomes

\[
R^{(a)}(s = (j,k,b,l,m)) = \begin{cases} 
1 - \frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}, & a = 0, k = 0; \\
1, & \text{otherwise}.
\end{cases}
\]

The proof is then divided into three parts as follows.

(i) If \( m = 0 \), the threshold is given by \( \varepsilon(j,k,l,m) = N_0 - 1 \) because the decoding is incorrect and the relay can only keep silent.

(ii) If \( k \neq 0 \) and \( m = 1 \), it can be shown from (18), (21) and (45) that for fixed \( j \) and \( l \), we get

\[
V^{(0)}_{n+1}(s = (j,k,b,l,m)) = V^{(a)}_{n+1}(s = (j,k,b,l,m)) = \lambda (E_{j,k,l,m} V_n(s = (j',k',\min(b+w,N_{b-1}),l',m'))) - V_n(s = (j',k',\min(b-a+w,N_{b-1}),l',m'))) \geq 0,
\]

for \( a \neq 0 \), and the inequality is valid due to the result obtained in Theorem 1. Thus, the action \( a = 0 \) is optimal in this case.

(iii) We define \( \Xi_n(s = (j,k,b,l,m)) = V^{(1)}_n(s = (j,k,b,l,m)) = V^{(0)}_n(s = (j,k,b,l,m)) \) and \( \Delta^{(0)}_n(s = (j,k,b,l,m)) = V^{(x)}_n(s = (j,k,b-1,l,m)) = V^{(y)}_n(s = (j,k,b,l,m)) \). For \( k = 0 \) and \( m = 1 \), it suffices to prove \( \varepsilon(j,k,l,m) = 0 \) by showing that \( \Xi_n(s = (j,k,b,l,m)) > 0 \) for all \( b \neq 0 \) and any \( n \) in the following. We first claim that at each value iteration \( n \),

\[
\Delta^{(0)}_n(s = (j',k',b',l',m')) > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}},
\]

for \( a \neq 0 \), which can be proved by induction in the following:

(a) Without loss of generality, we initialize \( V_0(s = (j',k',b',l',m')) = 0 \). For \( n = 1 \), by using (18) and (45), we get

\[
\Delta^{(0)}_1(s = (j',k',b',l',m')) = 0 > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}.
\]

In addition, we have

\[
\Xi_1(s = (j,k,b,l,m)) = \frac{N_0 K_{(0)}}{K_0^{(0)}} > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}.
\]

(b) Assume \( n = i \) holds. It then immediately implies from (48) that \( V_i^{(1)}(s = (j,k,b,l,m)) > V_i^{(0)}(s = (j,k,b,l,m)) \) for \( b \neq 0 \). On the other hand, it can be derived from (45) and Theorem 1 that

\[
V_i^{(1)}(s = (j,k,b,l,m)) \geq V_i^{(0)}(s = (j,k,b,l,m)) \geq 0.
\]

Since \( R^{(a)}(s = (j,k,b,l,m)) = 1 \) when \( a \neq 0 \). In conclusion, we get

\[
V_i(s = (j,k,b,l,m)) = \max \{ v_i^{(a)}(s = (j,k,b,l,m)) \} = V_i^{(1)}(s = (j,k,b,l,m)), b \neq 0.
\]

(c) For \( n = i + 1 \), it is obtained from (18), (21) and (45) that

\[
\Delta_i^{(0)}(s = (j',k',b',l',m')) = \lambda \cdot (E_{j',k',l',m'} \{ V_i(s = \tilde{j}, \tilde{k}, \min(b' + w, N_{b - 1}, l'), m')) - V_i(s = \tilde{j}, \tilde{k}, \min(b' + w, N_{b - 1}, l'), m') \}).
\]

From the optimal thresholds in the cases of (i) and (ii) and the discussions in (b), it yields

\[
V_i(s = \tilde{j}, \tilde{k}, b - 1, l, m)) = V_i(s = \tilde{j}, \tilde{k}, l, m)) |\begin{cases} 
\Delta_i^{(0)}(s = (\tilde{j}, \tilde{k}, b, l, m)) > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}, & m = 0; \\
\Delta_i^{(0)}(s = (\tilde{j}, \tilde{k}, b, l, m)) > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}, & \tilde{m} = 1, \tilde{k} = 0; \\
\Delta_i^{(0)}(s = (\tilde{j}, \tilde{k}, b, l, m)) > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}, & \tilde{m} = 1, k = 0, b = 1; \\
\Delta_i^{(0)}(s = (\tilde{j}, \tilde{k}, b, l, m)) > -\frac{N_0 K_{(0)}}{\mu_{sd} CM P_{sd} \rho_{sd}}, & \tilde{m} = 1, k = 0, b \geq 2,
\end{cases}
\]

where the first inequality and the second inequality are due to (47) at \( n = i \), the third equality is calculated from

\[
\Delta_i^{(0)}(s = (\tilde{j}, \tilde{k}, b, l, m)) = R^{(0)}(s = (\tilde{j}, \tilde{k}, b - 1, l, m)) - R^{(1)}(s = (\tilde{j}, \tilde{k}, b, l, m)),
\]

and the last inequality comes
from $\Delta_i^{(11)}(s = (j, k, \tilde{b}, \tilde{l}, \tilde{m})) = \Delta_i^{(00)}(s = (j, k, \tilde{b} - 1, \tilde{l}, \tilde{m}))$ and the claim of (47) at $n = i$. Using (49) and (50), we then have $\Delta_{i+1}^{(00)}(s = (j', k', b', l', m')) > \frac{N_0 K_0}{r}$. Furthermore, by definition, it leads to

$$E_{i+1}(s = (j, k, b, l, m))$$

$$= V_{i+1}^{(1)}(s = (j, k, b, l, m)) - V_{i+1}^{(0)}(s = (j, k, b, l, m))$$

$$= R^{(0)}(s = (j, k, b - 1, l, m)) - R^{(0)}(s = (j, k, b - 1, l, m))$$

$$+ V_{i+1}^{(1)}(s = (j, k, b, l, m)) - V_{i+1}^{(0)}(s = (j, k, b, l, m))$$

$$= R^{(1)}(s = (j, k, b, l, m)) - R^{(0)}(s = (j, k, b - 1, l, m))$$

$$+ \Delta_{i+1}^{(00)}(s = (j, k, b, l, m)) > 0,$$

for all $b \neq 0$. As a result, the optimal threshold in this case is given by $\varepsilon_j = 0$.

This theorem gives an important insight into understanding the optimal cooperative transmission strategy for the energy harvesting relay node at asymptotically high SNR regimes. Under this circumstance, the relay node with non-empty battery speeds its harvested energy only when the decoding is successful and the source node experiences the worst channel condition in its direct link. For a special case of $N_a = 2$, the optimal policy at asymptotically high SNR is simply given by

$$\pi^*(s = (j, k, b, l, m)) = \begin{cases} 1, & k = 0, b \geq 1, m = 1; \\ 0, & \text{otherwise.} \end{cases}$$

With the optimal cooperative transmission policy in Theorem 7, a theorem regarding the energy quantum supporting way for achieving the full diversity gain is provided in the following.

**Theorem 8:** The energy harvesting cooperative communications can achieve a diversity order of two, if and only if the energy quantum outage probability $P(E = 0 \mid Q_e = l) = 0$, for $l = 0, \ldots, N_e - 1$.

**Proof:** From Theorem 6, it suffices to prove this theorem by showing that $\rho = 0$ if and only if $P(E = 0 \mid Q_e = l) = 0$, for $l = 0, \ldots, N_e - 1$. By using (9), (10) and (20), the balance equation in (40) for the stationary state probability $p_s$ at the state $s = (0, 0, b', l', 1)$ can be rewritten as

$$P_{0,0,b',l',1} = \sum_{j=0}^{1} \sum_{k=0}^{N_e-1} \sum_{l=0}^{N_e-1} \sum_{m=0}^{N_e-1} P(H_{rd} = 0 \mid H_{sd} = j)$$

$$\cdot P(H_{sd} = 0 \mid H_{rd} = k) P(Q_e = l' \mid Q_e = l)$$

$$\cdot P(Q_e = 1 \mid Q_e = m)$$

$$N_e-1 \sum_{b=0}^{N_e-1} P_{\pi^*(s)}(Q_b = b' \mid Q_b = b, Q_e = l) p_{j,k,b,l,m}. \quad (53)$$

For the sufficiency part, since $\pi^*(s = (j, k, b, l, m)) \leq b$ and $P(E = 0 \mid Q_e = l) = 0$, for $l = 0, \ldots, N_e - 1$, it is obtained from (12) that

$$P_{\pi^*(s)}(Q_b = 0 \mid Q_b = b, Q_e = l) = P(E = -b + \pi^*(s) \mid Q_e = l) = 0,$$

where the harvested energy quantum must be non-negative, i.e., $P(E < 0 \mid Q_e = l) = 0$. By substituting (54) into (53), we can get $P_{0,0,0,0,1} = 0$. According to the optimal policy at asymptotically high SNR in Theorem 7 and the definition of $\rho$ in Theorem 4, it then implies

$$\rho = \sum_{s \in \Omega_{l,0}} p_s = \sum_{l=0}^{N_e-1} p_{0,0,0,0,1} = 0,$$

where the second equality is attributed to the definition of $\Omega_{l,0} = \{ s = (0, 0, b, l, m) \mid \pi^*(s) = a, b \in \mathbb{Q}, l \in \mathbb{Q} \}$.

For the necessity part, the condition $\rho = 0$ with the optimal policy at asymptotically high SNR in Theorem 7 requires $P_{0,0,0,0,1} = 0$, for $l' = 0, \ldots, N_e - 1$. From (53), the requirement of $P_{0,0,0,0,1} = 0$ implicitly indicates that $P_{\pi^*(s)}(Q_b = 0 \mid Q_b = 1, Q_e = l) = 0$ because the stationary state probability $p_{j,k,b,l,m}$ does not necessarily equal zero. Since $\pi^*(s = (0, 0, 1, l, l)) = 1$ at sufficiently high SNR, we can get

$$P_{\pi^*(s)}(Q_b = 0 \mid Q_b = 1, Q_e = l) = P(E = 0 \mid Q_e = l) = 0.$$

From Theorem 7 and Theorem 8, we know that any policy that obeys the threshold structure in (44) can achieve the same full diversity order but have different energy harvesting gains, if the energy quantum outage probability $P(E = 0 \mid Q_e = l) = 0$, for $l = 0, \ldots, N_e - 1$. Under this circumstance, the inactive and active probabilities are simply given as $S_0 = \mu_{rd} \mu_{sd} P(Q_0 = 0)$ and $\sum_{a=1}^{N_a - 1} S_a = \mu_{sd} \mu_{rd} P(Q_0 = 1)$ because $\rho = 0$. By using Theorem 3 and $P(Q_e = 1) = 1 - \frac{\gamma N_a}{P_N \eta}$, in the proof of Theorem 5, the asymptotic SER for the full-diversity achieving policy in (44) is therefore given as

$$P_{M, \text{asy}m} = \frac{(\mu_{rd} \mu_{sd} K_0^{(0,0)})}{c M \eta_{br} \eta_{bd}} + \frac{\sum_{a=1}^{N_a-1} S_a}{a} \left( \frac{P_s}{N_0} \right)^{-2}$$

$$\leq \frac{(\mu_{rd} \mu_{sd} K_0^{(0,0)})}{c M \eta_{br} \eta_{bd}} + \frac{\sum_{a=1}^{N_a-1} S_a}{c M \mu_{rd} \mu_{sd} \eta_{bd}} \left( \frac{P_s}{N_0} \right)^{-2}$$

$$- \frac{\gamma N_a}{c M \mu_{rd} \mu_{sd} \eta_{bd}} \left( \frac{P_s}{N_0} \right)^{-3},$$

where the upper bound is obtained from (42) by setting $\rho$ in $\Phi(1)$ as zero. It is worth noting that the above equality holds when the optimal policy for $N_a = 2$ in (52) is applied, and the corresponding energy harvesting gain is given by $\sqrt{c M \mu_{rd} \mu_{sd} \eta_{bd}} K_0^{(0,0)}$. From (55), to maximize the energy harvesting gain, one can appropriately design the non-zero power actions for the states $s = (j, 0, b, l, 1)$, for $b \geq 1$, by alternatively minimizing $\sum_{a=1}^{N_a-1} S_a$ subject to a sum probability constraint $\sum_{a=1}^{N_a-1} S_a = \mu_{sd} \mu_{rd} P(Q_0 = 1)$, which strikes a balance between the occurrence probability $S_0$ and the power scaling effect $\frac{1}{2}$. While the optimal policy for attaining the maximum diversity and energy harvesting gains can be acquired by the value iteration algorithm of the MDP, this analytical result suggests an aggressive way to spend the harvested energy for those states with non-zero power actions to obtain the better energy harvesting gain, since the power scaling effect usually dominates the occurrence probability.
In addition, Theorem 8 raises an interesting question of how to reach the energy quantum supporting condition of $P(E = 0 | Q_e = l) = 0$, for $l = 0, \ldots, N_e - 1$, in practice. We recall from [12] that the energy quantum outage probability $P(E = 0 | Q_e = l)$ in the real solar-data-driven energy harvesting model is given as

$$P(E = 0 | Q_e = l) = \left(1 - \frac{\bar{\mu}_l}{E_U}\right) g_1(\bar{\mu}_l, \bar{\rho}_l) - g_2(\bar{\mu}_l, \bar{\rho}_l),$$

(56)

where $\bar{\mu}_l$ and $\bar{\rho}_l$ are two underlying parameters which represent the mean and the variance of the random harvested energy at the $l^{th}$ energy harvesting state, respectively, and the functions $g_1(\bar{\mu}_l, \bar{\rho}_l)$ and $g_2(\bar{\mu}_l, \bar{\rho}_l)$ are defined as [12]

$$g_1(\bar{\mu}_l, \bar{\rho}_l) = \frac{1}{2} \left( \text{erfc} \left( \frac{-\bar{\mu}_l}{\sqrt{2} \bar{\rho}_l} \right) - \text{erfc} \left( \frac{1}{\sqrt{2} \bar{\rho}_l} (E_U - \bar{\mu}_l) \right) \right);$$

(57)

$$g_2(\bar{\mu}_l, \bar{\rho}_l) = \sqrt{\frac{\bar{\rho}_l}{2\pi E_U^2}} \left( \exp \left( -\frac{\bar{\mu}_l^2}{2\bar{\rho}_l} \right) - \exp \left( -\frac{1}{2\bar{\rho}_l} (E_U - \bar{\mu}_l)^2 \right) \right).$$

(58)

Notice that the larger the value $\bar{\mu}_l$, the better the energy harvesting condition, and the energy harvesting capability can be enhanced by increasing the values of some system parameters such as solar panel area, energy harvesting time duration and energy harvesting conversion efficiency, etc. Accordingly, we can find from (56)-(58) that the probability $P(E = 0 | Q_e = l)$ approaches to zero when $E_U \ll \bar{\mu}_l$, and this can be achieved by either reducing the energy quantum size or improving the energy harvesting capability.

V. NUMERICAL RESULTS AND DISCUSSIONS

In this section, some numerical examples are demonstrated to substantiate the analytical derivations and theorems for the energy harvesting cooperative communications. The simulation parameters are set as follows. In the cooperative communications, the policy management period $T_M$ is given as 300 sec, and the transmission power levels of the source node and the relay node (if active) are the same and equal to $P_s = G = 4 \times 10^4 \ \mu W$. Accordingly, the size of one energy quantum can be computed as $E_U = \frac{1}{2} G T_M = 6 \times 10^3 \ mJ$. The numbers of channel and battery states are set to three and eight, respectively. The channel quantization thresholds for the SD and the RD links are both randomly chosen as $\Gamma_{sd} = \Gamma_{rd} = \{0, 2, 0, 3, 0, \infty\}$, and it is assumed that the channels vary slowly with the normalized Doppler frequency $f_D = 5 \times 10^{-2}$. The decoding capability for the relay node is given by $\gamma = 15 \ dB$, which corresponds to a successful decoding probability of $0.95$ at $\frac{P_s}{N_0} = 28 \ dB$. The discount factor in the MDP is set close to unity, given by $\lambda = 0.99$. The adopted modulation schemes are quadrature-phase-shift keying (QPSK) and 8PSK. The solar-data-driven energy harvesting model in [12] is utilized to capture the influence of parameter settings on the system performance such as the solar panel size $\Omega$, the energy quantum size $E_U$, etc. The number of energy harvesting states is set as four, and the data record of the solar irradiance measured at the solar site in Elizabeth City State University in June from 2008 to 2010 is adopted for training the energy harvesting model in our simulation [28]. With the solar panel size $\Omega = 8 \ cm^2$ or $\Omega = 4 \ cm^2$ and the conversion efficiency for energy harvesting $\eta = 20 \ %$, the training results, including the energy harvesting state transition probability and the energy quantum harvesting probability, are listed in Table I. We note from Table I(b) and Table I(c) that the relay node has more opportunities to harvest a higher number of energy quanta when the panel size is expanded from $4 \ cm^2$ to $8 \ cm^2$. The above settings are used throughout the simulation, except as otherwise stated. When the value iteration algorithm is executed, the integrations in the reward functions (13)-(15) are carried out via a Riemann sum method.

Based on Theorem 7, two myopic policies which are able to achieve the full diversity order if the energy quantum outage probability is equal to zero are included in the simulation for performance comparison. Both of the two myopic policies abide by the same threshold structure as described in (44), but with different relay actions when the relay is active. The first one is an aggressive policy, called Myopic Policy I, in which the largest available energy in the battery is consumed for relaying the signals when the relay is active. Regarding the second one, called Myopic Policy II, the relay helps transmit the signals only at the lowest transmission power level when it is active.

Fig. 2 shows the performance comparison between the exact SER and the asymptotic SER for QPSK and 8PSK modulation schemes under various SNR values of $\Upsilon_{sr}$. With the obtained optimal policy, the exact SER is directly computed from (30) by applying the reward functions in (13)-(15) without any approximation, whereas the asymptotic SER is computed by using the approximate formula in (31). Just as mentioned in Theorem 3, we can observe from these two figures that the asymptotic SER is an upper bound for the exact SER, and our asymptotic results yield an excellent agreement with the exact curves in medium and high SNR regions. Hence, this expression is useful to correctly predict the characteristic of the SER performance for the energy harvesting cooperative communications in medium and high SNRs. Furthermore, the SER performance is improved as the operating SNRs $\Upsilon_{sr}$ and $\Upsilon_{sd}$ increase. We can make an interesting observation that for a fixed modulation scheme at $\Upsilon_{sr} = 30$ dB, the optimal policy with a larger number of affordable relay actions can achieve a better SER performance, but the performance curves, e.g., $N_a = 2$ and $N_a = 8$, become identical when $\Upsilon_{sd}$ is sufficiently high, no matter how many non-zero actions are available for the relay node.

Selected examples of the upper and lower bounds for the asymptotic SER under various values of $\Upsilon_{sr}$ for different modulation schemes: (a) QPSK and (b) 8PSK ($\Omega = 8$ cm$^2$).
level \( \rho \) and the stationary state probability for harvesting a huge number of energy quanta becomes very high and thus the occurrence probability \( \rho \) is almost zero stationary state probability \( \rho \) and a diversity order of two. In contrast, the diversity order for the exact SER is one. While the solar panel size is enlarged to \( \Omega = 8 \) cm\(^2\) and the basic transmission power level is set below \( G = 3 \times 10^4 \) \( \mu \)W, the slope of the asymptotic SER bears a resemblance to the performance curve with a diversity order of two. The reasons behind this can be explained as follows. As shown in Fig. 4(b) and Table I, when \( \Omega \) and \( G \) are sufficiently large and small, respectively, the average energy quantum outage probability \( \nu \) for the relay node is almost zero, thereby resulting in an almost zero stationary state probability \( \rho \) and a diversity order of two. In contrast, the diversity order for the energy harvesting cooperative communications turns out to be one when the stationary state probability \( \rho \) is not equal to zero.

Fig. 5 demonstrates the exact SER for the optimal policy and the two myopic policies under two different basic transmission power levels \( G \). The parameters of \( N_b \) and \( N_a \) are both set as eight, the solar panel size is given by \( \Omega = 8 \) cm\(^2\), and the adopted modulation scheme is QPSK. It is shown that for \( G = 3 \times 10^3 \) \( \mu \)W, the exact SER performance of the Myopic Policy II is comparable to that of the optimal policy, since the energy is spent conservatively in the Myopic Policy II and the stationary state probability \( \rho \) for which the relay runs out of the battery is very small. On the other hand, it can be seen that the Myopic Policy I performs worst than the optimal policy when the operating SNR becomes high due to the aggressive use of the energy, yielding a relatively large stationary state probability \( \rho \). For the case of \( G = 1 \times 10^2 \) \( \mu \)W, where the energy quantum outage probability becomes much close to zero, one can observe that the performance of the optimal policy is still superior to those of the two myopic policies, while they exhibit the same diversity order of two (reflected...
by the slope of the SER). This is because the optimal policy can achieve the maximum energy harvesting gain. Besides, it is found that the Myopic Policy I has an energy harvesting gain of about 4 dB in terms of 2 \log_2 \frac{P}{Q}$ over the Myopic Policy II due to the power scaling effect \frac{1}{\alpha}$ in (55).

VI. CONCLUSIONS

In this paper, we investigated the long-term average SER minimization problem for the DF cooperative communications with an energy harvesting relay node. By means of the MDP, we designed the optimal stochastic cooperative transmission scheme for the relay node that varies the transmission power with different energy harvesting, channel, battery, and decoding states. Closed-form expressions for the exact SER and the asymptotic SER of the proposed optimal cooperative transmission policy were analytically derived. Furthermore, we provided the SER upper and lower bounds to quantify the diversity order and the energy harvesting gain, which proves that a diversity order of two is guaranteed as long as the energy quantum outage probability is zero. We also explored a threshold-type structure for the cooperative transmission policies which are capable of achieving the full diversity, and examined the energy quantum supporting way which can lower the energy quantum outage probability in a practical energy harvesting model. The developed results and the effect of various system parameters on the SER performance were validated through extensive computer simulations. The design framework is useful toward understanding how to deploy the energy harvesting relays in cooperative networks as more efficiently as possible.
