**Problem formular**

- Let $x$, $y$, and $n$ denote noisy speech, clean speech, and additive noise.
- The corresponding signal model is
  \[ x = y + n \]
- The goal of speech enhancement is to get an estimation $\hat{y}$ of the clean speech $y$.
- Given observed noisy speech $x$, finding a function $f$ such that
  \[ \hat{y} = f(x) \approx y \]

**Example**

Left: clean speech spectrogram. Right: noisy speech spectrogram.
Related Works

- **Mapping or Masking**
  
- **Vocoder-based Speech enhancement**

Challenges of the existing methods

- Most deep learning-based speech enhancement methods operate directly on time-frequency representations or learned features without making use of the model of speech production.

- We need a speech enhancement method with clearer physical meaning and lower computational complexity.

- The computational complexity of the vocoder-based methods is too high to be applied in practice.

**Black Box Model**

**Motivation**

- **Source-filter Model of Speech Production**

  The discrete-time speech signal $s[n]$ is generated by a convolution of the excitation signal $e[n]$ and the vocal system $h[n]$

- **Neural Homomorphic Vocoder**

Integrating speech enhancement and the DSP-based vocoder into an ensemble has not been studied yet. Our contributions are as follows:

▸ We propose a new speech enhancement method that combines the advantages of DSP-based vocoder and complex-valued neural network based spectrum denoiser

▸ We investigate numerous loss functions and found that multi-resolution STFT loss benefits speech enhancement
### Proposed Method

#### Block Diagram

1. Segment speech waveform into frames
2. Transform time-domain signal into cepstral-domain via complex cepstrum analysis
3. Apply liftering to get the excitation and vocal tract

1. Transform the excitation and vocal tract cepstrum into time-domain via complex cepstrum inverse pipe-line
2. Apply circular convolution and post-processing to get the synthesized speech
Use complex neural networks to process the complex-valued spectrum

- Complex neural network is an extension of the real-valued neural network
- Let \( \mathbf{x} = x_r + jx_i \) be the input complex vector, and \( \mathbf{W} = W_r + jW_i \) be the weight matrix of the complex-valued Conv2d
- The complex-valued convolution is defined as
  \[
  \mathbf{W} \ast \mathbf{x} = (W_r \ast x_r - W_i \ast x_i) + j(W_i \ast x_r + W_r \ast x_i)
  \]

Excitation and vocal tract estimation with complex neural network

Complex neural network

- The network follows an U-Net architecture and applies complex recurrent network blocks for temporal modeling.
- When the connection is applied, the output of the neural network is considered to be a mask, an additional bounding process is applied.

\[ \hat{M}_{t,f} = |\hat{M}_{t,f}| \cdot e^{j\theta_{\hat{M}_{t,f}}} = \hat{M}_{t,f}^{mag} \cdot \hat{M}_{t,f}^{phase} \]
\[ \hat{M}_{t,f}^{mag} = \tanh(|O_{t,f}|), \quad \hat{M}_{t,f}^{phase} = O_{t,f} / |O_{t,f}| \]

We consider the following loss functions for neural network training:

- Scale Invariant SNR loss
  \[ L_{SI-SNR}(y, \hat{y}) = -10 \log 10 \left( \frac{\|y_{\text{target}}\|_2^2}{\|e_{\text{noise}}\|_2^2} \right) \]

- Weighted SDR loss
  \[ L_{wSDR}(x, y, \hat{y}) = \alpha L_{SDR}(y, \hat{y}) + (1-\alpha) L_{SDR}(n, \hat{n}) \]

- Multi-resolution STFT loss
  \[ L_{MR-STFT} = -\left( \|y - \hat{y}\|_1 + \sum_{i=1}^{I} L_{stft}^{(i)}(y, \hat{y}) \right) \]
  \[ L_{stft}^{(i)}(y, \hat{y}) = \frac{\|\|Y_i\| - \|\hat{Y}_i\|\|F}{\|Y_i\|_F} + \|\log |Y_i| - \log |\hat{Y}_i|\|_1} \]
Experiments

Datasets

- Speech: Chinese Standard Mandarin Speech Corpus\(^1\)
- Noise: DEMAND\(^2\)
- Four noise categories and one environment of each are selected as the training, validation, and seen-noise test set
- Another two noise categories are selected as unseen test data to evaluate the noise generalization
- The SNR levels for mixing the noisy speech are randomly sampled from a uniform distribution [-5dB, 10dB]

Experiments
Setups

- All the utterances are framed by a hamming window with a length of 32 ms and a hop size of 8 ms, and the FFT length is 512.
- The quefrency for separating the excitation and vocal tract is 29.
- The network architectures follow the setting of the DCCRN.
- The number of channel, kernel size and stride are set to \{16, 32, 64, 128, 128, 128\}, \((5,2)\) and \((2,1)\), respectively.
- For the proposed method, in order to alleviate cepstrum aliasing, the FFT size is increased to 2048.
The SI-SNR loss and wSDR loss yield comparable results in terms of PESQ and eSTOI.

The MR-STFT loss outperforms the SI-SNR and wSDR losses in terms of PESQ.

The proposed NHS-SE obtains the highest score in all metrics.

For the unseen noise types, the performance of all methods is degraded to some extent. However, the proposed method still outperforms all the others.

Experiments

Results: some failures

- We also conducted extra experiments using the proposed NHS-SE model with the SI-SNR and wSDR losses. However, the both models failed to converge.
- Synthesis-based method will cause phase mismatch, the proposed method failed to improve the SI-SNR score.
- Although the proposed method obtained the highest PESQ and eSTOI scores, there is some artificial noise in some case.
We proposed a novel speech enhancement method based on homomorphic analysis and synthesis.

It makes use of the advantages of the classical vocoder method and the recently popular speech enhancement method based on complex-valued neural networks.

The results demonstrated that the multi-resolution STFT loss performs better than the others in terms of PESQ and eSTOI.

Using the multi-resolution STFT loss, the proposed method outperforms state-of-the-art methods on both seen noise and unseen noise.

Future works include removing some artificial noise introduced by the synthesis procedure and studying speaker generalization of the models.
Thanks!
